

Early Decelerations

Decelerations which are caused by a parasympathetic response during labor can be benign in nature (a normal pattern occurrence) or can be abnormal or nonreassuring. They are identified visually on a fetal monitor tracing by when they occur in the contraction cycle either the onset or at the end of a contraction and also by their shape. An early deceleration is identified as a gradual decrease (onset to lowest point is ≥ 30 seconds) in fetal heart rate with return to the baseline associated with a contraction.

PLAY PICMONIC

Cause

Fetal Head Compression

[Fetus Head Compressed](#)

Fetal head compression is the most common cause of an early deceleration that occurs during labor as the fetal head advances in the birth canal.

Occurs During

Uterine Contractions

[Uterus Flexing](#)

Often during the first stage of labor (cervix dilated 4 to 7cm), an early deceleration can occur while the uterus is contracting.

Placement of Internal Mode of Monitoring

[Placing Internal Monitor](#)

The process of inserting an internal fetal monitor probe can lead to fetal head compression.

Vaginal Examination

[Vagina-violets](#)

During a vaginal exam, the presenting part is palpated which can lead to transient fetal head compression.

Fundal Pressure

[Pressing Funnel](#)

Applying external pressure on the laboring mother's abdomen is one mechanism that causes fundal pressure and fetal head compression, which leads to an early deceleration.

Considerations

Normal Pattern

[Normal Pattern](#)

An early deceleration is not associated with fetal hypoxemia, acidemia, or low Apgar scores. Consequently, there is no nursing intervention required other than continued monitoring.
